CSCI 104
Exceptions
Mark Redekopp
David Kempe
Code for Today

• On your VM:
  – $ mkdir except
  – $ cd except
  – $ wget http://ee.usc.edu/~redekopp/cs104/except.tar
  – $ tar xvf except.tar
Recall

- Remember the List ADT as embodied by the 'vector' class
- Now consider error conditions
  - What member functions could cause an error?
  - How do I communicate the error to the user?

```cpp
#ifndef INTVECTOR_H
#define INTVECTOR_H

class IntVector {
    public:
    IntVector();
    ~IntVector();
    void push_back(int val);
    void insert(int loc, int val);
    bool remove(int val);
    int pop(int loc);
    int& at(int loc) const;
    bool empty() const;
    int size() const;
    void clear();
    int find(int val) const;
};
#endif
```

int_vector.h
Insert() Error

• What if I insert to a non-existent location

```c++
#include "int_vector.h"
void IntVector::insert(int loc, int val)
{
    // Invalid location
    if(loc > size_){
        // What should I do?
    }
}
```

insert(7, 99);

We can hijack the return value and return an error code.

But how does the client know what those codes mean? What if I change those codes?
get() Error

- What if I try to get an item at an invalid location

```cpp
#include "int_vector.h"
int IntVector::get(int loc)
{
    // Invalid location
    if(loc >= size_){
        // What should I do?
    }
    return data_[loc];
}
```

get(7);

I can't use the return value, since it's already being used.
Could provide another reference parameter, but that's clunky.
int get(int loc, int &error);
EXCEPTIONS
Exception Handling

• When something goes wrong in one of your functions, how should you notify the function caller?
  – Return a special value from the function?
  – Return a bool indicating success/failure?
  – Set a global variable?
  – Print out an error message?
  – Print an error and exit the program?
  – Set a failure flag somewhere (like “cin” does)?
  – Handle the problem and just don't tell the caller?
What Should I do?

• There's something wrong with all those options...
  – You should **always** notify the caller something happened. Silence is not an option.
  – What if something goes wrong in a Constructor?
    • You don't have a return value available
  – What if the function where the error happens isn't equipped to handle the error

• All the previous strategies are **passive**. They require the caller to actively check if something went wrong.

• You shouldn't necessarily handle the error yourself...the caller may want to deal with it?
The "assert" Statement

- The **assert** statement allows you to make sure certain conditions are true and immediately halt your program if they're not
  - Good sanity checks for development/testing
  - Not ideal for an end product

```cpp
#include <cassert>

int divide(int num, int denom)
{
    assert(denom != 0);
    // if false, exit program

    return(num/denom);
}
```
Exception Handling

- Use C++ Exceptions!!
- Give the function caller a choice on how (or if) they want to handle an error
  - Don't assume you know what the caller wants
- Decouple and CLEARLY separate the exception processing logic from the normal control flow of the code
- They make for much cleaner code (usually)

```cpp
// try function call
int retVal = doit();
if(retVal == 0){
}
else if(retVal < 0){
}
else {
}
```

Which portion of the if statement is for error handling vs. actual follow-on operations to be performed.
The "throw" Statement

- Used when code has encountered a problem, but the current code can't handle that problem itself
- 'throw' interrupts the normal flow of execution and can return a value
  - Like 'return' but special
  - If no piece of code deals with it, the program will terminate
  - Gives the caller the opportunity to catch and handle it

- What can you give to the throw statement?
  - Anything (int, string, etc.)! But some things are better than others...

```c++
int main(){
    int x; cin >> x;
    divide(5,x);
}

int divide(int num, int denom)
{
    if(denom == 0)
    {
        throw denom;
        return(num/denom);
    }
```
The "try" and "catch" Statements

- try & catch are the companions to throw
- A try block surrounds the calling of any code that may throw an exception
- A catch block lets you handle exceptions if a throw does happen
  - You can have multiple catch blocks...but think of catch like an overloaded function where they must be differentiated based on number and type of parameters.

```c
int divide(int num, int denom) {
    if (denom == 0)
        throw denom;
    return(num/denom);
}

try {
    x = divide(numerator, denominator);
}
catch(int badValue) {
    cerr << "Can't use value " << badValue << endl;
    x = 0;
}
```
The "try" & "catch" Flow

• `catch(...)` is like an 'else' or default clause that will catch any thrown type
• This example is not good style...we would never throw something deliberately in our try block...it just illustrates the concept

```cpp
try {
    cout << "This code is fine." << endl;
    throw 0;  //some code that always throws
    cout << "This will never print." << endl;
}
catch(int &x) {
    cerr << "The throw immediately comes here." << endl;
}
catch(string &y) {
    cerr << "We won't hit this catch." << endl;
}
catch(...) {
    cerr << "Printed if the type thrown doesn't match";
    cerr << " any catch clauses" << endl;
}
cout << "Everything goes back to normal here." << endl;
```
Catch & The Stack

• When an exception is thrown, the program will work its way up the stack of function calls until it hits a catch() block

• If no catch() block exists in the call stack, the program will quit

```cpp
int divide(int num, int denom) {
    if(denom == 0)
        throw denom;
    return(num/denom);
}
int f1(int x) {
    return divide(x, x-2);
}
int main() {
    int res, a;
    cin >> a;
    try {
        res = f1(a);
    }
    catch(int& v) {
        cout << "Problem!" << endl;
    }
}
```
Catch & The Stack

• When an exception is thrown, the program will work its way up the stack of function calls until it hits a catch() block

• If no catch() block exists in the call stack, the program will quit

```cpp
int divide(int num, int denom)
{
    if(denom == 0)
        throw denom;
    return(num/denom);
}
int f1(int x)
{
    return divide(x, x-2);
}
int main()
{
    int res, a = 2;
    try {
        res = f1(a);
    }
    catch(int& v) {
        cout << "Problem!" << endl;
    }
}
```
Catch & The Stack

• When an exception is thrown, the program will work its way up the stack of function calls until it hits a catch() block
• If no catch() block exists in the call stack, the program will quit

```cpp
int divide(int num, int denom)
{
    if(denom == 0)
        throw denom;
    return(num/denom);
}
int f1(int x)
{
    return divide(x, x-2);
}
int main()
{
    int res, a;
    cin >> a;
    try {
        res = f1(a);
    }catch(int & v) {
        cout << "Caught here" << endl;
    }
}
```
Catch & The Stack

• You can use catch() blocks to actually resolve the problem

```cpp
int divide(int num, int denom) {
    if(denom == 0)
        throw denom;
    return(num/denom);
}
int f1(int x) {
    return divide(x, x-2);
}

int main() {
    int res, a;
    cin >> a;
    while(1){
        try {
            res = f1(a);
            break;
        }
        catch(int& v) {
            cin >> a;  
        }
    }
}
```
What Should You "Throw"

- Usually, don't throw primitive values (e.g. an “int”)
  - `throw 123;`
  - The value that is thrown may not always be meaningful
  - Provides no other context (what happened & where?)

- Usually, don't throw “string”
  - `throw "Someone passed in a 0 and stuff broke!";`
  - Works for a human, but not much help to an application

- Use a class, some are defined already in `<stdexcept>` header file
  - `throw std::invalid_argument("Denominator can't be 0!");`
  - `throw std::runtime_error("Epic Fail!");`
  - Serves as the basis for building your own exceptions
  - Have a method called “what()” with extra details
  - You can always make your own exception class too!
Exception class types

- exception
  - logic_error (something that could be avoided by the programmer)
    - invalid_argument
    - length_error
    - out_of_range
  - runtime_error (something that can't be detected until runtime)
    - overflow_error
    - underflow_error

#include <iostream>
#include <stdexcept>
using namespace std;
int divide(int num, int denom)
{
    if(denom == 0)
        throw invalid_argument("Div by 0");
    return(num/denom);
}
int f1(int x)
{
    return divide(x, x-2);
}

int main()
{
    int res, a;
    cin >> a;
    while(1){
        try {
            res = f1(a);
            break;
        }
        catch(invalid_argument& e) {
            cout << e.what() << endl;
            cin >> a;
        }
    }
}
#include <iostream>
using namespace std;

int main()
{
    int number = 0;
    cout << "Enter a number: ";
    cin >> number;

    if(cin.fail()) {
        cerr << "That was not a number." << endl;
        cin.clear();
        cin.ignore(1000, '\n');
    }
}

#include <iostream>
using namespace std;

int main()
{
    cin.exceptions(ios::failbit); //tell "cin" it should throw
    int number = 0;
    try {
        cout << "Enter a number: ";
        cin >> number;       // cin may throw if can't get an int
    }
    catch(ios::failure& ex) {
        cerr << "That was not a number." << endl;
        cin.clear();
        // clear out the buffer until a '\n'
        cin.ignore( std::numeric_limits<int>::max(), '\n');
    }
}

Vector Indexing (Old Way)

```cpp
#include <iostream>
#include <vector>
using namespace std;

int main()
{
    int index = -1;
    vector<int> list(5);

    if(index < 0 || index >= list.size()) {
        cerr << "Your index was out of range!" << endl;
    }
    else {
        cout << "Value is: " << list[index] << endl;
    }
}
```
#include <iostream>
#include <vector>
#include <stdexcept>
using namespace std;

int main()
{
    int index = -1;
    vector<int> list(5);
    try {
        cout << "Value is: " << list[index] << endl;
    } 
    catch(out_of_range &ex) {
        cerr << "Your index was out of range!" << endl;
    }
}
Notes

• Where does break go in each case?
• In 2nd option, if there is an exception, will we break?
  – No, an exception immediately ejects from the try {...} and
goes to the catch {...}

```cpp
do {
    cout << "Enter an int: ";
    cin >> x;
    if( ! cin.fail()){  
        break;
    }  
    else {  
        cin.clear();
        cin.ignore(1000,'\n');
    }  
} while(1);
```

```cpp
do {
    cin.exceptions(ios::failbit);
    cout << "Enter an int: ";
    try {
        cin >> x;
        break;
    } catch(ios::failure& ex) {
        cerr << "Error" << endl;
        cin.clear();
        cin.ignore(1000,'\n');
    }
} while(1);
```
Other "throw"/"catch" Notes

- Do not use throw from a destructor. Your code will go into an inconsistent (and unpleasant) state. Or just crash.

- You can re-throw an exception you've caught
  - Useful if you want to take intermediate action, but can't actually handle the exception
  - Exceptions will propagate up the call hierarchy ("Unwinding the call stack")

```cpp
#include <iostream>
#include <stdexcept>
using namespace std;

int divide(int num, int denom)
{
    if(denom == 0)
        throw invalid_argument("Div by 0");
    return(num/denom);
}

int f1(int x)
{
    int y;
    try { y = divide(x, x-2); }
    catch(invalid_argument & e){
        cout << "Caught first here!" << endl;
        throw; // throws 'e' again
    }
}

int main()
{
    int res, a;
    cin >> a;
    while(1){
        try {
            res = f1(a);
            break;
        }
        catch(invalid_argument & e) {
            cout << "Caught again" << endl;
            cin >> a;
        }
    }
}
```
Other Exceptions Notes

- Think about where you want to handle the error
  - If you can handle it, handle it...
  - If you can't, then let the caller

```cpp
#include <iostream>
#include <stdexcept>
using namespace std;

int f1(char* filename)
{
    ifstream ifile;
    ifile.exceptions(ios::failbit);
    // will throw if opening fails
    ifile.open(filename);

    // Should you catch exception here
    // Or should you catch it in main()
}

int main(int argc, char* argv[])
{
    readFile(argv[1]);
    ...
}
```
